Internet Collaboration on Extremely Difficult Problems: Research versus Olympiad Questions on the Polymath Site

Isabel Kloumann Chenhao Tan Jon Kleinberg Lillian Lee Cornell University imk36@cornell.edu,{chenhao|kleinber|llee}@cs.cornell.edu

ABSTRACT

Despite the existence of highly successful Internet collaborations on complex projects, including open-source software, little is known about how Internet collaborations work for solving "extremely" difficult problems, such as open-ended research questions. We quantitatively investigate a series of efforts known as the *Polymath* projects, which tackle mathematical research problems through open online discussion. A key analytical insight is that we can contrast the polymath projects with *mini-polymaths* — spinoffs that were conducted in the same manner as the polymaths but aimed at addressing math Olympiad questions, which, while quite difficult, are known to be feasible.

Our comparative analysis shifts between three elements of the projects: the roles and relationships of the authors, the temporal dynamics of how the projects evolved, and the linguistic properties of the discussions themselves. We find interesting differences between the two domains through each of these analyses, and present these analyses as a template to facilitate comparison between Polymath and other domains for collaboration and communication. We also develop models that have strong performance in distinguishing research-level comments based on any of our groups of features. Finally, we examine whether comments representing research breakthroughs can be recognized more effectively based on their intrinsic features, or by the (re-)actions of others, and find With a growing number of sites where people congregate to discuss solutions to hard problems, it is useful to also appreciate the basic similarities between Polymath and other Web-based communication and collaboration platforms. Even if the specific findings about Polymath do not generalize to all other contexts, the questions themselves can often be generalized. With this in mind, an additional goal of the paper, beyond the investigation of Polymath as a domain, is to present a template for questions that we believe can be productively asked in general about the type of data that sites like Polymath generate. We hope that this template will help facilitate direct comparisons and contrasts with future studies of collaborative Web-based problem-solving.

1.1 Summary of contributions

Data from Polymath 1 was analyzed in an interesting paper by Cranshaw and Kittur [2]; in their own words, they provide "an indepth descriptive analysis of data gathered from [Polymath 1]," focusing on the role of leadership in the progress of the project, and the interaction between established members and newcomers as the projects proceeded. With the inception of eight new Polymath projects, and rich variation in their evolution and success, a new set of opportunities arises in the type of questions we can explore with Polymath data. We organize our analysis around *two central questions* regarding Polymath.

(1) Research or hard problem-solving?

At a general level, our first question is to analyze some of the distinctions between online discussion about open research questions versus online discussion about tasks where the outcome is more attainable.

To address this question, and to make the comparison as sharp as possible, we use a source of discussion data that comes from Polymath itself: the mini-polymath projects. Shortly after Polymath was successfully underway, Terence Tao assembled a group to solve something hard but more manageable than a research question; each mini-polymath problem is a question from a past International Mathematical Olympiad (IMO). The existence of the minipolymaths provides us with a very natural contrast between the two types of activities. Specifically, we can understand the differences between tackling an open-ended research problem, where current techniques may be completely inadequate for finding a solution, vs. solving a problem that, while difficult, is known to be feasible, in a setting where, to a large degree, there is control for topic (in both cases, difficult mathematics) and for participants (there are dozens of people who participated in both Polymath and the mini-polymaths). We study and contrast the polymath and minipolymath projects with three lenses: the roles and relationships of the authors, the temporal evolution of the projects, and the linguistic properties of the comments.

Roles of authors and leadership. First, we analyze the role of the authors, the role of leadership, and differences in patterns of conversation networks in the two domains. In particular, in the research domain we observe that there is a substantially higher concentration of activity in the hands of fewer people, indicating that there was a more distinct notion of contribution leadership in the research domain than the somewhat easier mini-polymath domain. We further observe that there is significantly more symmetry in the global conversation network than what would be initially expected, which is not the case in the mini-polymath projects.

Temporal dynamics. Second, we consider how progress in the two domains evolved over time, and observe interesting patterns both in differences and similarities between the two domains. The two types of projects differ in the temporal properties of the dis-

cussion: overall, comments come more quickly in mini-polymath projects, befitting their smaller-scale format, but, interestingly and unexpectedly, on the shortest time scales comments actually come more quickly in Polymath, indicating that the research discussions have the potential to reach the most rapid-fire rate.

Linguistic properties. Third, we study the use of language in the two domains, in both content and high-level linguistic features such as politeness, relevance, and specificity, again finding interesting differences between the two domains. Strong signals in the text distinguish comments in Polymath projects from those in minipolymath projects. At the most naive level, using bag-of-words classification achieves an accuracy above 90%, since problem-specific terms and time differences (as expressed by words such as "primes" or "July") can be prominent in these two kinds of discussions. But surprisingly, and more importantly, restricting attention to just words that are not topic-focused still achieves 90% accuracy, suggesting stylistic differences in Polymath comments and mini-polymath comments. Additionally, high-level linguistic features beyond just individual words display significant differences between the two domains: research discussions in Polymath projects have higher average word distinctiveness, higher relevance to the original post for the topic, greater politeness, and greater usage of the past tense.

(2) General contribution or research highlight?

Our second question is based on a key aspect of research collaborations — they pass through "milestones" when important progress is made. Can we characterize such milestones as the collaboration unfolds? With the ability to do this, one may be able to set up mechanisms that help researchers focus on promising directions, which can potentially result in more productive research collaboration. Alternatively, a more pessimistic hypothesis is that these milestones may only be realized in retrospect. To characterize these milestones, we formulate a prediction problem that asks whether it is possible to identify comments that were marked "highlights" by participants.

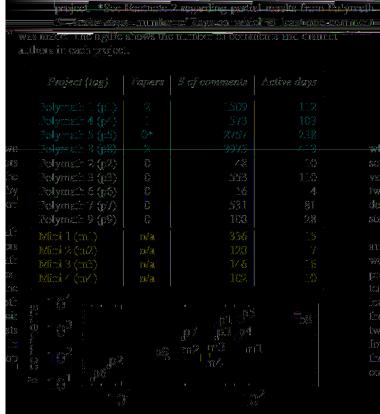

The task of identifying highlights turns out to be more challenging than our first task, distinguishing Polymath comments from mini-polymath ones. Nevertheless, we still obtain prediction performance significantly above the baselines for the task. To help understand whether the challenge is inherently in the task or in the shortcomings of our prediction algorithms, we compared to the performance of applied mathematics graduate students in recognizing highlights from Polymath discussions. Algorithms using the strongest feature sets achieve comparable performance to these human judges. We also find that features based on the individual comments themselves outperform features that try to capture reactions or the run-ups to the comments in question.

2. DATA

The Polymath and mini-polymath projects share their common roots in a gateway wiki hosted by Michael Nielsen¹. Starting from that site, we parsed all discussion comments, and for each comment retained its text, its author's WordPress username, its timestamp (with minute-level granularity), and its permalink.

For portions of our analysis we use all the Polymath projects, but in other parts we focus on the most active and successful. As Table 1 indicates, there is a relatively wide variation in the amount of content produced as part of each Polymath project, as well as variation in their levels of success. The mini-polymaths, on the other hand, are more uniform and each solved the Olympiad problem that

¹http://goo.gl/LVEWbe

ef oxoor

an by the corre

distinct authors

they feaused on. When comparing Polymath to mini polymeth, we often feaused on the subset of Polymath projects whose successful cuteomes are analogous to the successes of the mini-polymaths; these are the Folymaths that led to publications (Polymaths 1, 4, and 8) as well as Folymath 5 which was also highly active and led to important partial results on the Erices Discrepancy Problem (1009).² Unless otherwise stated when we refer to gassifiative results or observations about the Polymath projects, we are referring to this subset.

In addition, we collected data about which community in the Poly consthill project wore identified as mesarch highlights, which was directrical on a subjects of the holymath projects with pages² ne. The data studied in this paper has been made publicly available.

comment, denoted $\mathcal{A} = \{a^i\}_{i=1}^n$, and the sequence S in which their m comments were made: $S = \{a_1^i, a_2^j, \dots\}$. The random baseline for these metrics will be based on a time-zone-controlled random sequence. That is, to create a random sequence S^{rand} , for position S_i^{rand} , we select a random author from the set of authors who have commented in that hour of the day, proportional to how frequently they have commented during that hour.

Definition: reply symmetry. To define reply symmetry we consider the reply matrix A: A_{ij} is the number of times author j follows author i in the sequence S. We then define symmetry in the matrix as $sym(A) = 1 - \frac{|A - A^T|_1}{|A|_1}$. The 1-norm of the matrix A, $|A|_1$, is the total number of comments, and $|A - A^T|_1$ is the num-

In the author sequence, we first count the number of times we observe the sequence motif aba — an author a is followed by another author b, who is then followed again by a. Similarly, the motif abccorresponds to comments by three distinct authors in succession, while the motif aaa corresponds to three comments in a row by the same author. We define *stickiness* of the interaction to be the extent to which the *aba* motif is overrepresented; it is the probability of observing the motif *aba* in the real sequence relative to the probability of observing it in a time-zone-controlled random baseline (the likelihood ratio).

Results: symmetry and stickiness in research domains. In Figure 2 we test the hypothesis that the amount of symmetry observed is as much as would be observed by a random, asymmetric graph.

up to time t_i . Then the project's instantaneous velocity and acceleration are the first and second time derivatives of x(t), which can be measured using the central difference formula: $v(t_i) = x'(t_i) \approx \frac{x(t_{i+1}) - x(t_{i-1})}{x(t_{i-1})}$, and similarly for $a(t_i) = v'(t_i)$. We compute

 $t_{i+1} - t_{i-1}$, and similarly for $a(v_i) = v(v_i)$, we compare the average velocity with units of comments per minute, providing a summary measure of how rapidly each project progressed. The average acceleration then has units of comments per minute per minute, and tells us whether or not the speed of the project was picking up (positive acceleration) or slowing down (negative acceleration).

Finally, we introduce the notion of a comment's *momentum*: borrowing from physics, the momentum of an object is the product of its mass and its velocity. We interpret the number of characters in a comment as its mass and so compute the momentum as the product of a comment's length and its velocity. This notion of momentum enables us to distinguish between projects with, for example, the same commenting *rate* but with different average comment *lengths*. **High-momentum projects pick up more speed.** Surprisingly, in Figure 3 (bottom) we find that all Polymath and mini-polymath projects have a positive average acceleration. Earlier we observed that comment response times were on average faster in mini-polymath than in Polymath; we also observe that they tend to have higher acceleration

Perhaps most strikingly, in Figure 3 (bottom), we see that the average acceleration and momentum in this case have an approximately monotonic relationship with each other, meaning that the projects with the highest momentum were also the projects that were picking up the most speed. This monotonic relationship is not something to be expected a priori: for example, a project that started off with long, rapid comments and slowly decayed would have high average momentum and negative acceleration; but all of the examples observed here have the opposite pattern, with the higher momentum projects accelerating more rapidly.

5. LINGUISTIC FEATURES

Following the plan outlined in the introduction, we continue by studying the distinctions between Polymath projects — representing research on open problems — and mini-polymath projects, which are efforts to solve Math Olympiad problems. This investigation offers the opportunity to understand the contrasts between these related but qualitatively different types of collaborative activities. In this section, we introduce the high-level linguistic features that we consider and the differences observed in how they manifest in the two domains.

5.1 Exploring high-level linguistic features

Our set of high-level linguistic features draws on recent innovations in natural language processing that have been used for applications including the memorability of movie quotes [3], the effects of wording on message propagation [16] and the popularity of online posts [12]. We supplement these features with several more basic ones as well.

We divide the features into four groups: relevance, distinctiveness, politeness and generality. To get an initial understanding of how these features differ between Polymath and mini-polymath projects, for each one we conduct a t-test between feature values extracted from Polymath comments and mini-polymath comments (Table 4). We find that Polymath comments are indeed significantly different in many of these features compared to minipolymath comments. Later in §6, we will see how they perform in a prediction setting in comparison to topic-based linguistic feaTable 4: T-test results for high-level linguistic features. For each feature, we conduct a t-test from two independent samples, extracted from Polymath comments and mini-polymath comments respectively, where the null hypothesis is that the two kinds of comments come from the same distribution. The number of arrows in the table visually indicates the *p*-value magnitude: p < 0.05: 1 arrow, p < 0.01: 2 arrows, p < 0.001: 3 arrows, p < 0.0001: 4 arrows. \uparrow indicates that Polymath comments have larger values; \downarrow indicates that mini-polymath comments have larger values.

tures, as well as the role- and temporal-based features discussed in §3 and §4.

We begin by describing the feature-level differences between Polymath and mini-polymath comments. For each category of differences, we summarize it first in a bold-faced sentence and then elaborate in the subsequent paragraph.

Research discussions match the original problems more closely. We first ask how much the language used in the discussion drifts away from the language used at the outset of the project to describe the problem. We do this by computing Jaccard similarity between each comment and the original post for the project. Since the discussions are segmented into *threads* of roughly 100 consecutive comments each, we also compute a related measure — the Jaccard similarity between each comment and the initial post in the thread it belongs to.

One might expect that since research discussions are open-ended, the language might drift quickly away from the description of the initial problem. In fact, we find that comments are significantly more similar to the original posts for Polymath projects, both in the original problem description and in the current post.

Research discussions have *less* **distinctive language.** One might expect the language in tackling hard research problems to be more "distinct" from daily language compared to that in solving problems with known solutions. We formalize distinctiveness using language model scores, defined as the average logarithm of word probabilities [3, 12, 16]. Our language model, based on frequencies of one, two, and three word sequences (unigrams, bigrams, and trigrams) of words and part-of-speech tags, is developed from the Brown corpus [11].

Perhaps somewhat surprisingly, research discussions resemble daily language more in terms of part-of-speech tag patterns. When

- Linguistic features. The linguistic features consist of *non-topical features* (denoted "nt-ling") listed in the first four bullet points, and *topical features* (denoted "topic ling") listed in the latter two bullet points.
- (nt ling) High-level linguistic features, as discussed in §5.1: politeness, generality, specificity, hedging, fraction of *novel* words with respect to the entire preceding conversation or to a fixed-size window of previous comments.
- (nt ling) LIWC. Linguistic Inquiry and Word Count (LIWC) includes a dictionary of words classified into different categories, along dimensions that include affective and cognitive properties [15]. We use the frequency of each LIWC category in a comment as features.
- (nt ling) Part-of-speech tags (POS). Part-of-speech tags can provide us with stylistic information for a comment. All possible part-of-speech tags are considered as features.⁶.
- (nt ling) Stopwords from the NLTK⁷; most frequent 50 words from the training data; most frequent 100 words from training data.
- (topic ling) Bag-of-words (BOW). This is a very strong method typically used in natural language processing tasks. We include all the unigrams that occur at least 5 times in our training data as features. We use the tokenizer from the NLTK package after replacing urls and MathJax scripts with special tokens.
- (topic ling) Bag-of-words for the preceding and succeeding comments. The same definition as the feature above, but now for each of the five comments before the comment in question, and each of the five after.

Computational evaluation of prediction. We use 5-fold crossvalidation in our computations to measure prediction performance. Since the task is balanced, we use accuracy as our evaluation metric. In the computations, for each feature set, we extract the values from each comment in a pair, and then take the differences between the first comment and the second comment in this pair. For BOW and POS based features, we normalize the feature vectors using L2norms, while for the other features, the values are linearly scaled to [0, 1] based on training data. We use scikit-learn in all prediction computations.⁸

Prediction: Roles, Temporal. In Figure 4 we observe that using the anonymized roles (author motifs as discussed in §3.2) offers good performance. This positive performance may be due to the distinctions we observed above. In particular, the Polymath projects tend to have larger and significant correlations in the reply structure of the comment threads.

We also observe that the temporal features offer significant improvements over the random baseline. As with the role features, this performance increase can potentially be understood as thanks to the substantial differences in temporal dynamics in the two projects that we discussed in §4.

Linguistic prediction performance: topical vs. non-topical. We make several observations about the prediction results based on linguistic-only features. First, all the feature sets improve on the length baseline for both the uncontrolled task (when we form a pair for each mini-polymath comment) and the controlled task (when

Table 5: Top 20 features in Polymath vs. mini-polymath prediction. Features are separated by spaces. High-level linguistic features are in quotes. Other non-topical features are named by concatenating the category name and feature name; for instance, "POS-adj" means the feature "adjectives" from the part-of-speech category.

we match the author and approximately match the length within each pair).

Second, the bag-of-words feature set slightly outperforms the non-topic feature set on the uncontrolled task, but when we add length and author controls, in fact the non-topic feature set significantly outperforms the bag-of-words features, achieving close to 90% accuracy. It is interesting that the non-topic feature set should achieve this, since it is not attuned to the content of the comments themselves. Moreover, the non-topic features actually give better performance on the controlled task than on the uncontrolled task, despite the fact that the controlled task was set up to limit the effectiveness of various features; meanwhile, the performance of the bag-of-words feature set in the controlled task (along with stop-words and POS) drops significantly.

As for individual categories, high-level linguistic features actually outperform all other non-topical categories despite the small number of features in this category, including commonly used LIWC features. This observation is robust across both tasks. It is worth noting that there are fewer high-level linguistic features than POS or LIWC features.

In terms of top features (Table 5), similarity to the original problem statement is the most prominent signal for Polymath comments, followed by part-of-speech tags including adjectives; in contrast, LIWC categories and part-of-speech tags tend to be top indicators of mini-polymath comments. Table 5 also shows the top word-level features that emerged for the bag-of-words feature set, including topical words such as "sequence", "prime" and "mine"⁹.

7. IDENTIFYING RESEARCH HIGHLIGHTS: INTRINSIC VS. CONTEXTUAL EVIDENCE

We now investigate the second main question we posed in the introduction: Are research breakthroughs identifiable in a string of comments? If they are, can one best recognize them solely from their content, a finding that could indicate that authors know the eventual importance of their statements? Or are breakthroughs best

⁶Througout we use the NLTK maximum entropy tagger with default parameters, which is based on the Penn Treebank Dataset (http://www.cis.upenn.edu/~treebank/ home.html)

important-looking comment in a pair than to judge a single text in isolation. Third, describing (B) allows us to be more concise than describing (A), where mechanisms for handling class imbalance would need to be explained. We note, though, that (B) gives us less data to work with (since we can only construct as many pairs as there are highlights), and doesn't directly map onto the application of classifying individual comments as they naturally appear.

Feature sets and cross validation. For this task, we use the same feature sets that we employed for our first task of distingishing Polymath comments from mini-polymath comments. These features are described in §6. Further, in all experiments, we employ the same experiment protocol as in the first task. Random guessing yields a baseline accuracy of 50%.

7.1 **Prediction Performance**

Jerfrenze

To assess the difficulty of the task for humans as a point of comparison for our algorithmic performance, we asked three Applied Mathematics graduate students to attempt the classification task

nological system, the participants, and the overall collaboration as the project advanced from its uncertain beginning to a successful conclusion.

In addition to Barany's piece, Cranshaw and Kittur [2] provide a quantitative overview of Polymath 1. They find that activity tends to spur other activity, and that activity by either of the two leaders, Terence Tao and Tim Gowers, tends to spur even more activity. They observed that the numbering-threading convention was successful in allowing multiple threads to develop simultaneously, but that cross-references were limited. By constructing the comment mention-graph and cross-referencing authors' Wordpress profiles with Google Scholar accounts they were able to show that, while the top two contributors were the Fields Medalists, there were much "smaller names" close behind - indicating that Gowers's vision of the project being accessible to a broad audience was achieved at least in part.

Finally, mini-polymath has been studied by Pease and Martin [14]; they show how the approaches there follow well-studied frameworks for problem-solving.

¹⁰http://goo.gl/ijbIqP. The page's revision history reveals that Tao's intent was indeed to list "highlights", but he switched to the milder term "events" to alleviate Gowers' apparent embarrassment at one of his contributions being deemed "highlight-worthy".

¹¹At the time, we had not installed the length controls, but the task is strictly easier when length is a potential clue.

9. CONCLUSION

Polymath is an interesting experiment in promoting Internet collaboration on a type of activity — working on open mathematical research problems — that is otherwise not really represented in large open online collaborative efforts. Using this site as a lens, we have sought to contrast Internet collaborations on open research problems with Internet collaborations on "merely" difficult problems.

Limitations. While Polymath is the most visible effort at open Internet collaboration on mathematical research problems, one should be careful about generalizing too far from a single domain. Moreover, we can ask whether there are specific aspects of Polymath that played a role in the findings. Perhaps most importantly, the participation guidelines of the main Polymaths promoted rapid, incremental posting over the arguably more typical research mode wherein one engages in longer periods of off-line reflection and independent thought. The (laudable) intent was to make the project more accessible, but it is possible that the collaboration was less natural as a result. Regardless of these concerns, of course, it is clear that several projects had successful outcomes, resulting in publications and/or important partial progress toward the stated goal.

Future Directions. Many of our findings open up promising future directions. First, the reply-time properties are interesting, with the intriguing fact that Polymath, which is significantly slower than Mini-Polymath overall, becomes faster at the shortest time scales. We would like to understand the reason for this fast pace; it is also natural to ask whether this "organically" developed fast pace is good for collaborations, or whether it is more effective to proceed more slowly at the shortest time scales. It is also interesting to ask whether we can trace any potential effects that the high-level linguistic properties have on the trajectory of the discussion or the quality of the outcome.

Finally, our second prediction task, on identifying highlights in real time, raises potential questions for the design of future iterations of Polymath-style sites. If it were possible to flag predicted highlights as they happen, is this a useful thing to make explicit for a group engaged in research? And if so, is it more productive to call attention to these predicted highlights as they happen, or at a later point? Questions in this style point to the potential opportunities for algorithms trained on this type of data to assist in guiding future discussions, when on-line groups assemble to work on hard problems together.

Acknowledgments. We thank the students that took the course CS6742 (Fall 2014) at Cornell and the anonymous reviewers for helpful comments. We also particularly thank John Chavis, Zachary Clawson, Stephen Cowpar, David Eriksson, Hyung Joo Park, and Evan Randles for serving as judges in the prediction tasks. This work was supported in part by NSF grant IIS-0910664, a Simons Investigator Award, a Google Research Grant, a Facebook fellow-ship, and a NSF Graduate Research Fellowship.
